MODELLING HEALTH INDICATORS IN A JOINT FRAMEWORK VIA FACTOR COPULA MODELS¹

(Artykuł nadesłany: 07.06.2016 r.; Zaakceptowany: 21.07.2016 r.)

ABSTRACT

The problems of ageing societies in advanced economies have recently put emphasis on the evaluation of health of the elderly. Health is likely to determine job market activity of the increasing parts of the society. Appropriate modeling of health conditions is therefore key for policymaking, in particular given that detailed health data are now available via ageing surveys. Recently, there has been increased interest in modeling multiple ordinal health data. Makdisi and Yazbeck (2014) utilize the counting approach, which requires the transformation of multiple category health indicators into binary and lead to the loss of information but also changes the dependence structure. We offer a different approach which does not have these limitations and is feasible for highdimensional data (while, for example, stochastic dominance methods are inconclusive for many dimensions (Duclos and Echevin 2012). We use recently developed methods based on so-called vine pair-copula constructions (PCC) (Aas et al. 2009). We estimate a 1-factor copula model (Nikoloulopoulos and Joe 2015) for 24 health indicators taken from English Longitudinal Study of Ageing (ELSA) such as self-reported health status, mobility, eyesight, hearing and pain rating and questions related to emotional health. We show that there are substantial interdependencies in health data which cannot be neglected by

dichotomization and aggregation, nor can they be detected by the standard multivariate probit model. t(4)- and t(5)- factor copula model provides the best fit, and items that measure general optimism are most informative of the underlying factor. Groups are most heterogeneous along the employment status, with retired and disabled groups showing significantly more dependence than other groups in items related to mobility and general health status.

Keywords: multiple health indicators; interdependence; factor copulas; vine copulas.

JEL Classification: I31, D63

INTRODUCTION

Nowadays, there are increasingly many health indicators available in health and ageing surveys. Such surveys include detailed information on functional limitations, cognitive, emotional and mental health, and health measurements such as hypertension, biomarkers etc. However, there are two major measurement problems in using this vast information. Firstly, researchers often restrict to self-assessed health only (van Doorslaer et al. 1997; van Doorslaer and Koolman 2004; Kunst et al. 2004; Cutler et al. 2015) or they aggregate various health indicators into a single index of health (e.g. Makdisi and Yazbeck 2014) or analyze various health indicators separately. This means that the dependence structure is ignored, which means the loss of substantial part of the information on the health distribution. With fixed margins, generally, the more association between dimensions of wellbeing, the more inequality (Atkinson and Bourguignon 1982), because of higher likelihood for individuals to suffer from multiple deprivations. Interdependencies thus help to identify opportunities for policy intervention with the largest efficiency gains. This is particularly relevant for patients suffering from multiple chronic diseases, which given ageing population will become even more of a focus for public health policy and spending.

Secondly, aggregation imposes some form of cardinalization of an often ordinal indicator (e.g. Mackenbach et al. 2008). Many health indicators are ordinal e.g. widely used self-reported health status, problems with vision, hearing, communication, speech, cognition, the feeling of pain, anxiety, depression etc. Cardinalization of ordinal variables has been criticized by Allison and Foster (2004). The choice of a particular numerical transformation (i.e. scale) of an ordinal indicator is arbitrary, on the other hand, the mean and the variance are not invariant to monotone transformations. Therefore, the results may be often easily reversed when a different scale is chosen as examples by Allison and Foster (2004), Apouey and Silber (2013), Bond and Lang (2014) and Kobus (2015) show. This is the main drawback of the standard approach to measuring socioeconomic inequalities in health, namely, concentration curves, which is developed for ratio-scale variables and should not be used directly with ordinal data,

as rightly criticized by Makdisi and Yazbeck (2014). Inequality measurement theory has been extended to account for ordinality of the data, but so far mostly for one health indicator (Allison and Foster 2004; Apouey 2007; Abul Naga and Yalcin 2008; Kobus and Miłoś 2012; Apouey and Silber 2013; Lazar and Silber 2013; Abul Naga and Stapenhurst 2015; Cowell and Flachaire 2015; Gravel et al. 2015; Lv et al. 2015; Kobus 2015). There are very few contributions up to date for multivariate health data – Sonne Schmidt et al. (2015) propose criteria for comparing distributions which are only tractable in the case of two binary indicators, so their applicability is very restricted. Duclos and Echevin (2012) propose a robust method for measuring health-income gradient based on dominance conditions. However, it is unlikely that dominance conditions are conclusive for 40 health indicators which are available for example in ageing surveys. Therefore, while elegant, these methods may provide little help for applied health economists.

The most comprehensive treatment of multiple health categories was offered recently by Makdisi and Yazbeck (2014). They use the insight from the counting approach to multidimensional poverty to measure the width of health problems i.e. the number of health problems. This further requires transforming each health indicator into a binary variable. They analyze the US and Canadian data on vision, hearing, speech, emotion and other health indicators and transform them into 0-1 variables. For example, vision problems are recorded as 1 (the person has vision problems) if he or she has difficulty seeing with glasses. Dichotomization leads to a substantial loss of information. Moreover, it obscures the dependence structure. The goal of this paper is to show that interdependencies should not be easily neglected in case of categorical health data. To this end, we use recently developed factor copula models (Nikoloulopoulos and Joe 2015). These models omit some of the difficulties we mentioned, because they allow for a flexible modeling of multivariate distributions and are appropriate for modeling high-dimensional data. Although we cannot fully account for the ordinality of health data (i.e. in the margins), copula approach enables scale-free modeling of the dependence structure. We utilize 24 health indicators from Wave 1 and 6 of English Longitudinal Study of Ageing (ELSA) and provide evidence for stronger dependence of health indicators for both lack of health problems (lower tail dependence) and severe health problems (upper tail dependence). Thus we obtain a complex picture of health among the elderly, which cannot be fully reflected by the counting approach, and is enough to justify a truly multivariate approach to modeling health data.

In more detail, factor copula models we utilize are inspired by the modeling approach based on pair-copula constructions (PCC). PCC allows to model the dependence between each two dimensions via bivariate copulas which are building blocks of a multivariate copula. Such decomposition of a multivariate distribution into bivariate elements lowers substantially the level of integration² and

² Denoting by d the number of dimensions, instead of d-dimensional integral, with PCC one deals with d unidimensional integrals.

makes maximum likelihood estimation feasible for high-dimensional data. Furthermore, distributions with tail dependence and asymmetric tail dependence can be accommodated using PCC, and such detailed picture of various interdependencies present in the data provides key information for efficient targeting of most vulnerable groups (multiply deprived). As Atkinson (2011, p. 326) states: "The copula diagram is helpful in thinking about policies to moderate the social gradient of health." For example, let us assume that it turns out that for low socioeconomic status (SES) correlation between BMI and diabetes is stronger than for people with high SES. Yet the true picture may be that in fact for low BMI, SES is not important and dependence between BMI and diabetes is the same independent of SES, whereas it is for high BMI that dependence between BMI and diabetes is much higher for low SES than for high SES, so intervention should target only this group. That is to say, dependence in lower tail (low BMI) is different from the dependence in upper tail (high BMI); methods based on multivariate normal distribution and correlation cannot detect this. As another example, it is likely that dependence between cognitive and mental health indicators might be different from the dependence between physical and mental health indicators; a modeling approach should allow for such heterogeneity.

The methods used here can be thought of as a generalization of a standard approach to multivariate modeling based on multivariate normal distribution (MVN). MVN is a good premise, as many phenomena in nature evince Gaussian distribution. It arises as a limit of a scaled sum of weakly dependent random variables with no variable dominating, i.e. Central Limit Theorem. It is constructed using the property that any linear combination of independent Gaussian random variables is Gaussian. As such, it is simple and tractable. However, its limitations such as a requirement of normal margins, lack of negative dependence and tail dependence, are important from the point of view of applications. Overuse of Gaussian distribution in risk modeling is criticized, especially in the last few years, it was even called "The formula that killed Wall Street" in a famous article by Felix Salmon published in Wired magazine. Particularly in finance, income dispersion is typically uneven or there may exist stock market shares which are dependent only when they reach high values. To model tail dependence appropriately is key for effective portfolio diversification. Tail dependence is a property that indicates how the joint probability behaves in extreme, low or high, values. Upper(lower) tail dependence means that large(low) values of two or more variables occur together more often. Multivariate Gaussian distribution does not have tail dependence, mass is clustered in the centre, tails are symmetrical and carry little mass, so they may underestimate the risk. These problems occur both on univariate and joint levels, so the mismatch caused by applying MVN is compounded when the number of dimensions increases. Therefore non-Gaussian models might be more appropriate in risk analysis, insurance, finance and economics. The study of copulas is one way to enter a non-Gaussian world.

A copula is a multivariate probability distribution function with uniform marginals. It is popular due to the celebrated Sklar's theorem (Sklar 1959) which states that a copula and marginal distribution characterize the joint distribution. For continuous distributions such representation is unique. Thus, copula can be thought of as a method to construct joint distributions from marginal distributions. This modeling approach has the advantage of having univariate margins of different types (e.g. with potentially different scale/shape parameters) and the dependence structure can be modeled separately from univariate margins, which leads to more efficient estimation. It is indeed much more flexible than wellknown families of multivariate distributions such as normal, t, Pareto and others. Thus, copulas allow for two-step estimation where the two steps are independent. First, univariate margins are chosen and they can be any – e.g. univariate Gaussian and t for retaining symmetry, gamma for exponential tails, Pareto for heavy tails, Poisson for integer-valued data etc. Uniform margins are obtained via probability integral transform and in the second step copula is fit to the joint data. It can be chosen flexibly to model different types of dependence structure (e.g. exchangeable, conditional independence, both positive and negative dependence) and different types of joint tail behavior (e.g. upper tail dependence, lower tail dependence, asymmetric tail dependence).

Despite theoretical elegance, building high-dimensional copulas is considered a difficult problem (Aas et al. 2009). However, this problem has been addressed recently by proposing the called vine pair copula constructions (Aas et al. 2009). The principle is to decompose a multivariate distribution into a series of bivariate copulas applied to original variables and to their conditional distribution functions. An example will help to present this concept. Let $X = (X_1, X_2, X_3)$. Its density $f(x_1, x_2, x_3)$ can be factorised i.e. $f(x_1, x_2, x_3) = f_1(x_1) f(x_1 | x_2) f(x_1 | x_2, x_3)$. On the other hand, given that $F(x_1, x_2, x_3) = C(F_1(x_1), F_2(x_2), F_3(x_3))$ we can write joint density as

$$f(x_1, x_2, x_3) = c_{123}(F_1(x_1), F_2(x_2), F_3(x_3)) f_3(x_3) f_2(x_2) f_1(x_1),$$

where $c_{123}(F_1(x_1), F_2(x_2), F_3(x_3))$ is a 3-variate copula density. Further, we get

$$\begin{split} f(x_1,x_2) &= c_{12}(F_1(x_1),F_2(x_2)) \, f_1(x_1) \, f_2(x_2) \\ \text{and} \, f(x_1|x_2) &= \frac{f(x_1,x_2)}{f_2(x_2)} = c_{12}(F_1(x_1),F_2(x_2)) \, f_1(x_1). \end{split}$$

We can also express $f(x_1|x_2, x_3)$ as

$$\begin{split} f(x_1|x_2,x_3) &= C_{13|2}\left(F(x_1|x_2),F(x_3|x_2)\right)f(x_1|x_2) = \\ &= C_{13|2}(F(x_1|x_2),F(x_3|x_2))c_{12}(F_1(x_1),F_2(x_2))f_1(x_1). \end{split}$$

Continuing this we arrive at

$$\begin{split} f(x_1,x_2,x_3) &= f_1(x_1) \, f_2(x_2) \, f_3(x_3) c_{12}(F_1(x_1),\, F_2(x_2)) c_{23}(F_2(x_2),\, F_3(x_3)) \, \times \\ &\quad \times c_{13\,|\,2}(F(x_1\,|\,x_2),\, F(x_3\,|\,x_2)). \end{split}$$

Altogether, this means that we can model multivariate distribution by having bivariate copulas as building blocks. Dependence between each two dimensions can be modeled flexibly and computation is fast. Such decomposition can be presented graphically (Bedford 2002) and is called the *regular* vine. Our vine has 3 variables and two trees: first tree in which variables 1 and 2 as well as 2 and 3 are connected via bivariate linking copulas, and second tree in which variables 1 and 3 are connected via a bivariate linking copula conditional on 2. If at some tree bivariate linking copulas become independence copula we say that the vine is truncated. Factor copulas (Nikoloulopoulos and Joe 2015) presented here are such truncated vines, however (Nikoloulopoulos and Joe 2015) develop them as conditional independence model and we follow this presentation.

We find that factor copula models based on t(4) and t(5) copulas provide better fit than standard multivariate normal model, which is a special case of models developed here. This suggest that our variables are generated as a mixture of discreticised means which is typical for a sample which is a mixture of heterogeneous groups. Furthermore, this suggests that there is enough dependence structure in categorical health data that cannot be easily neglected. Such interdependencies cannot be detected with the counting approach and we show a simple example of how such an approach obscures the dependence structure. These interdependencies are present in all analyzed group distributions which supports a joint modeling framework for health data. The strongest dependence is with the items that express general optimism and such is the interpretation of the underlying factor. The groups defined along the employment status dimension are the most heterogeneous. For retired and disabled people the strongest dependence with the underlying factor is observed for self-reported health status and mobility, whereas for the employed group items seem to be linked to the factor more equally. Altogether, this paper shows that there are substantial dependencies in health data which cannot be easily neglected. Furthermore, the modeling approach offered here is feasible for high-dimensional data.

The paper is organized as follows. Section 1 presents copula theory, with particular emphasis on ordinal data and factor copula models. In Section 1 we present the dataset and the results of estimating 1-factor copula models. Finally, we conclude (Section 1) by pointing to future research on improving modeling of high-dimensional health distributions.

1. THEORETICAL MODEL AND ITS ESTIMATION

Before we present factor copula models that are suited for ordinal data we start with basic definitions related to copula theory. We start with bivariate copulas, but generalizations to multivariate copulas are straightforward (Nelsen 2006). The presentation of copula theory is based on Nelsen (2006) and Joe (2015).

1.1. DEFINITIONS

Let F, G be cumulative distribution functions. Let $X \sim F$ and $Y \sim G$. It is a well-known fact that if $X \sim F$ is a continuous random variable, then $F(X) \sim U(0,1)$. If $U \sim U(0,1)$ and F is a univariate cdf and F^{-1} is its generalised inverse, then $X = F^{-1}(U) \sim F$. Here X can be continuous or discrete. Moreover, for $U \sim U(0,1)$ and $V \sim U(0,1)$ we obtain by the inversion two independent samples from F and G, which are $X = F^{-1}(U)$ and $Y = G^{-1}(V)$ respectively.

Definition 1. Let $U \sim U(0,1)$, $V \sim U(0,1)$, $X \sim F$ and $Y \sim G$. Additionally, let $(X,Y) \sim H$. If H is continuous, then $(U,V) = (F(X),G(Y)) \sim C$ where C is a copula.

By definition, there are two marginal variables with cdfs and a function that combines these cdfs to return bivariate distribution. A copula is therefore a bivariate, or, in general, a multivariate distribution function whose margins are uniform. By Sklar's theorem, such function exists and is unique for continuous variables:

Theorem 1. Let H be a bivariate cdf with univariate marginal cdfs, F and G. Then, there exists a bivariate copula C such that H(x, y) = C(F(x), G(y)) for all $(x, y) \in \mathbb{R}$ And conversely, if F and G are univariate continuous random variables, then C(F(x), G(x)) is a bivariate distribution for (X, Y) with marginal distributions F and G, respectively.

Theorem 1 ensures uniqueness of copula only for continuous distributions. For discrete distributions there is a whole set of copulas which agree with Sklar's representation H(x,y) = C(F(x),G(y)). The problems related to copulas for discrete distributions are described in Genest, Nešlehová (2007). Despite numerous problems, these authors conclude that "copula modelling remains a valid option for constructing multivariate distributions with discrete margins" (p. 507) and their article in fact shows that rank-based inference for copula parameters is not recommended in the discrete case. Here we deal with ordinal data that have mostly discrete distributions.³ To be precise, we deal with data that are ordinal, i.e. invariant to monotone transformations, and discrete, i.e. probability mass is concentrated on a finite number of points. In the discrete case copula function is determined uniquely on intersections of F(x), G(y) where x = 0, ..., K - 1 and y = 0, ..., L - 1 with K and L being the number of categories of, respectively, x and y. We have:

$$F(y_1, ..., y_d) = C(F_1(y_1), ..., F_d(y_d)) \text{ for } y_i \in \{0, ..., K-1\}$$
 (1)

which leads to

$$C(u_1, ..., u_d) = F(F_1^{-1}(u_1), ..., F_d^{-1}(u_d)) \text{ for } u_i \in [0, 1]$$
 (2)

Copulas are particularly well-suited to study the dependence of ordinal data. As Schweizer (1981) note, "it is precisely the copula which captures those properties of the joint distribution which are invariant under (...) strictly increasing

³ This is not always the case, e.g. BMI is an ordinal variable, test scores too, and they both have continuous distributions.

transformations". With ordinal variables the only relevant information we have is about the ordering, therefore it is a very desirable property of a dependence measure to not change when the variable is transformed by a monotone transformation.

Not surprisingly, copula which takes marginal cdf values has this property, i.e. if C_{XY} is a copula function corresponding to the bivariate distribution of random variables X, Y and f, g are strictly monotonic continuous functions, then $C_{f(X)g(Y)} = C_{XY}$. For other monotonic transformations of X, Y the copula's behaviour is also known – for f increasing and g decreasing $C_{f(X)g(Y)}(u,v) = u - C_{XY}(u,1-v)$ and for both f and g strictly decreasing it holds that $C_{f(X)g(Y)}(u,v) = u + v - 1 + C_{XY}(1-u,1-v)$.

As mentioned before, copulas enable appropriate modeling of tail dependence. We will now define these concepts formally.

A bivariate copula C is reflection symmetric if for all $0 \le u_1, u_2 \le 1$ and den-

sity
$$c(u_1, u_2) = \frac{\partial^2 C(u_1, u_2)}{\partial u_1 \partial u_2}$$
 it holds that $c(u_1, u_2) = c(1 - u_1, 1 - u_2)$. Otherwise,

we say that C is reflection asymmetric and has more probability in the upper or lower tail. Upper tail dependence focuses on the upper quadrant of the distribution. It is measured by the upper tail dependence coefficient $\lambda_U \in [0,1]$:

$$\lambda_U = \lim_{U \to 1} -\left(\frac{C(u, u)}{1 - u}\right) \tag{3}$$

If the limit exists and equals 0, then C does not have upper tail dependence. If $\lambda_U \in (0,1]$, then C has upper tail dependence. Similarly, if the limit given by:

$$\lambda_L = \lim_{U \to 0} + \left(\frac{C(u, u)}{u}\right) \tag{4}$$

exists, then C has lower tail dependence for $\lambda_L \in (0,1]$ and no lower tail dependence for $\lambda_L = 0$.

Only scale-invariant measures of association are suitable for ordinal data. These are, for example, widely known association coefficients such as Kendall's tau or Spearman's rho. They are in fact measures based on the copula. Here we use Kendall's tau.

Definition 2. (19) Let X and Y be continuous random variables with a copula C. Then the population version of Kendall's τ for X and Y is given by

$$\tau(X, Y) = -1 + 4 \int_0^1 \int_0^1 C(u, v) dC(u, v)$$

The sample version of Kendall's tau is defined in terms of concordance. Each pair of observations from the sample $\{(x_1, y_1), ..., (x_n, y_n)\}$ is either concordant (i.e.

$$x_i > x_j, y_i > y_j$$
 or $x_i < x_j, y_i < y_j$) or discordant (i.e. $x_i > x_j, y_i < y_j$ or $x_i < x_j, y_i > y_j$).

Kendall's tau is then the difference in the number of concordant and discordant pairs divided by the number of all pairs. Here we use Kendall's tau because copula models with different parameters are not directly comparable, therefore parameter estimates and standard errors need to be compared on a Kendall's tau scale.

The dependence parameters θ vary across copula families. In order to compare different models, it is necessary to calculate Kendall's τ . The following transformation of copula parameters applies to Gaussian t copulas with $\theta \in (-1,1)$ (Hult 2002)

$$\tau = \frac{2}{\pi}\arcsin\theta,\tag{5}$$

whereas the following transformation applies to Gumbel copula with $\theta \in [1,\infty)$ (Genest 1986)

$$\tau = 1 - \frac{1}{\theta},\tag{6}$$

Therefore, Kendall's τ for Gaussian and t copulas range from -1 to 1, and as for Gumbel, $\tau \in (0, 1)$, because this copula models only positive dependence.

1.2. PARAMETRIC COPULA FAMILIES

Parametric copula families are most commonly used for their convenient properties (Joe 2015), i.e. they are easy to implement numerically as they have closed forms that do not contain integrals. Three copula families are considered due to their distinctive attributes: multivariate normal copulas, *t* copulas and Gumbel copulas, as well as related copulas, such as survival Gumbel (i.e. Gumbel copula rotated by 180 degrees to model lower tail dependence instead of upper tail dependence characteristic for Gumbel). Normal and *t* copulas are called elliptical copulas and Gumbel is a special case of an Archimedean copula. In describing various data generating processes that lead to particular families of copulas we follow intuition given by Nikoloulopoulos and Joe (2015).

Let *d* be the number of (ordinal) variables whose multivariate distribution we would like to model. The first family, further referred to as Gaussian, presents reflection symmetry and no tail dependence which means that it is suitable when the data has been generated through some process of averaging (Nikoloulopoulos and Joe 2015) e.g. in answering a question a respondent is taking an average experience from all the events in his life relevant to this particular question. Gaussian copula is a good modeling choice when we expect the majority of respondents to fall into the middle categories with little fluctuation. Gaussian copula is defined in the following way

$$C(\vec{u}; \Sigma) = \Phi_d(\Phi^{-1}(u_1), ..., \Phi^{-1}(u_d); \Sigma)$$
 (7)

where $\vec{u} \in [0,1]^d$ and Σ is a $d \times d$ correlation matrix that serves as a parameter. For a bivariate copula, there is only one parameter $\theta \in (-1, 1)$:

$$C(u, v; \theta) = \Phi_2(\Phi^{-1}(u), \Phi^{-1}(v); \theta)$$
 (8)

There is always one parameter needed for each pair of variables. For Gaussian copula, both $\lambda_L = \lambda_U = 0$.

t copulas, as opposed to Gaussian copulas, cluster more probabilistic mass on the tails, simultaneously keeping the focus in the centre. Not only is it possible to set different degrees of freedom ν for the margins, but also to control skewness. t copulas model answers which are generated as combinations of means. This happens when respondents are of mixed populations, e.g. differ in sex or locations. Let t be univariate Student's t distribution cdf with ν degrees of freedom. Then, a multivariate t copula has the following form:

$$C(\vec{u}, \Sigma, \nu) = T_{d, \nu}(T_{\nu}^{-1}(u_1), ..., T_{\nu}^{-1}(u_d); \Sigma)$$
(9)

where Σ is positive definite parametric matrix. With $\nu \to \infty$, a Gaussian copula is obtained and for small values of ν there is more probability in the joint upper and lower tails.

For the bivariate case, $\Sigma = \begin{bmatrix} 1 & \theta \\ \theta & 1 \end{bmatrix}$ where $-1 < \theta < 1$ and the copula cdf is:

$$C(u, v; \theta, \nu) = T_{2,\nu}(T_{\nu}^{-1}(u), T_{\nu}^{-1}(v); \theta)$$
(10)

Tails are symmetrical and the dependence coefficients can be written as:

$$\lambda_U = \lambda_L = 2T_{\nu+1} \left(-\frac{\sqrt{\nu+1}\sqrt{1-\theta}}{\sqrt{1+\theta}} \right) \tag{11}$$

where t stands for t Student cdf.

Gumbel copula family, on the other hand, is characterized by larger dependence in the upper tail, meaning that probability mass of the joint distribution is shifted towards the extreme values. These copulas capture only positive dependence. If two margins of K categories display negative dependence, one of them should be recoded from K-1 to 0 in order to use Gumbel copula. Such extreme value copulas are a good fit for responses derived from best-case or worst-case scenarios. For example, when asked about mobility limitation, the respondent takes into account only events when his or her disability prevented them from performing some actions and based on this he or she chooses lower categories. In other words, he or she takes the minimum value of all the events relevant to the question.

Bivariate Gumbel copula with parameter θ is the following:

$$C(u, v; \theta) = e^{-((-\ln u)^{\theta} + (-\ln v)^{\theta})^{\frac{1}{\overline{\theta}}}}, \tag{12}$$

where $1 \le \theta < \infty$.

We can rotate a Gumbel copula by 180° and thus obtain lower tail dependence; such transformation is called survival Gumbel or reflected Gumbel copula.

If $(U, V) \sim C$ for bivariate C, then $(1 - U, 1 - V) \sim C_r$ and $C_r(u, v) = u + v - 1 + C(1 - u, 1 - v)$.

Therefore, the survival Gumbel has the following form:

$$C(u, v; \theta) = u + v - 1 + e^{-((-\ln u)^{\theta} + (-\ln v)^{\theta})\frac{1}{\theta}}$$
(13)

Other possibilities include rotations by 90° and 270° to model negative dependence.

$$C_{90^{\circ}}(u, v) = v - C(1 - u, v) \tag{14}$$

$$C_{270^{\circ}}(u, v) = u - C(u, 1 - v)$$
 (15)

Figure 1. Contour plots of bivariate copulas with different behaviour in the tails

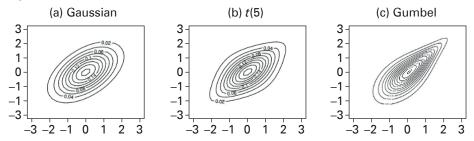

Figure 1 illustrates the support of different copulas. The isolines are sets of points with the same probability. There is more dependence in the tails if the mass is more concentrated around the diagonal. Gaussian copula does not have this property and Gumbel copula has it for higher values i.e. in the upper tail. For *t* copula tail dependence is symmetric.

1.3. FACTOR COPULAS. 1-FACTOR COPULA MODEL

Inspired by the vine copula approach, Nikoloulopoulos and Joe (2015) propose so-called factor copula models for multivariate ordinal data. These are latent variable models for the analysis of high-dimensional item response data in which dependence comes from latent (unobservable) factors. This happens, for example, when there are 40–50 items in a questionnaire but some of them are associated as they aim to model the same concept (e.g. anxiety, depression). The theoretical concept is low-dimensional so latent (factor) models are suitable. The most well-known is the standard multivariate normal model. It is a special case of models proposed by (Nikoloulopoulos and Joe 2015) where all bivariate linking copulas are Gaussian copulas. Factor copula models can be interpreted as latent maxima/minima (in comparison to latent means) and as such they place more probability mass in the tails than a model based on multivariate normal distribution. For the first factor there are bivariate copulas that link each observed item (ordinal variable) with the latent factor, and for the second factor there are bivariate copulas that link each observed item with the

second factor *conditional* on the first factor. As mentioned before, the connection with vine copulas is that such factor models are in fact truncated vine copulas. However, following Nikoloulopoulos and Joe (2015) we will motivate them as conditional independence models. An important computational advantage of factor copula models and the reason why Joe (2015) describes them as the best modeling choice for multivariate data, is the need to estimate $\mathcal{O}(d)$ parameters instead of $\mathcal{O}(d^4)^5$.

Definition 3. Let $Y_i = (Y_{i1}, ..., Y_{id})$ be a vector of d ordinal variables each measured on a scale $\{0, ..., K-1\}$. The p-factor model assumes conditional independence of $Y_p,..., Y_d$ given latent variables $X_p,..., X_p$ (factors). The joint probability mass function (pmf) is therefore:

$$P(Y_1 = y_1, ..., Y_d = y_d) = \int \prod_{j=1}^d P(Y_j = y_j | X_1 = x_1, ..., X_p = x_p) dF_{X_1, ..., X_p}(x_1, ..., x_p)$$

where F_{X_1, \dots, X_n} is the joint distribution of latent factors.

The conditional independence assumption allows us to replace d-dimensional integrals with the multiplication of one-dimensional integrals. Copulas appear in how $P(Y_j = y_j \mid X_1 = x_1, ..., X_p = x_p)$ is modeled. Here we present and estimate 1-factor copula model. Further research will focus on estimating 2-factor models for health data as well as more complex structured factor copula models (Krupskii and Joe 2015), which preserve the group structure, e.g. some items are by design more associated than others. As in a standard model for ordinal data, factors gain their interpretation from the items they connect to the most, i.e. via higher values of copula dependence parameters. For example, in case of health data one might expect items such as physical health and mobility to fall in one category (i.e. relate to one underlying factor), whereas items such as depression and anxiety to fall in a different category (i.e. relate to the other underlying factor). The factors are assumed to be independent to ease identifiability. Factor copula models do not have closed form cdfs, however, each of the d items is connected to each factor with a bivariate parametric copula, and typically no more than 2 factors are used. Moreover, the model allows mixtures of copula families, so the dependence between each two items is modeled flexibly.

A significant feature of factor copulas is that they inherit tail dependence (Hua 2014). If, for example, bivariate distributions of items j, k and factor X, namely, bivariate distributions of (Y_j, X) and (Y_k, X) are characterized by more probability in the upper tail, then (Y_j, X) also has upper tail dependence. Therefore, one can infer from bivariate margins of the distribution of $Y = (Y_1, \ldots, Y_d)$ which copula families should be used with the data. If upper tail depend-

⁴ They do not have to be independent for more complex structured factor copula models (14)

⁵ Or other copulas with properties similar to Gumbel like Galambos or Clayton.

⁶ They do not have to be independent for more complex structured factor copula models (Krupskii and Joe 2015).

ence is observed in (Y_j, Y_k) , then a Gumbel copula should be used both with (Y_j, X) and (Y_k, X) .

Let the cutpoints in the U(0, 1) scale be $a_{jk} = \Phi((\zeta_{jk}))$ where ζ_{jk} are corresponding cutpoints in the N(0, 1) scale for j = 1, ..., d. Let X be a latent variable, $X \sim U(0, 1)$. Given Theorem 1 there exists a copula C_j such that $F_{(X, Y_j)}(x, y_j) = C_j(x, F_{Y_j}(y_j))$. Then, the conditional cdf is the following

$$F_{Y_{j}|X}(y_{j}|x) = P(Y_{j} = y_{j}|X = x) = \frac{\partial C_{j}(x, F_{Y_{j}}(y_{j}))}{\partial x} := C_{j|X}(a_{j, y_{j}+1}|x)$$
(16)

and we have that

$$P(Y_1 = y_1, ..., Y_d = y_d) = \int_0^1 \prod_{j=1}^d P(Y_j = y_j | X = x) dx = \int_0^1 \prod_{j=1}^d (C_{j|X}(a_{j,y_j+1} | x)) dx + C_{j|X}(a_{j,y_j} | x)) dx$$

$$(17)$$

Clearly, $C_{j|X}(a_{j,y_j+1}|x) - C_{j|X}(a_{j,y_j}|x)$ gives the probability of $Y_j = y_j$ conditional on X = x. We have d items so d bivariate linking copulas, so d parameters to estimate.

1.4. TWO-STEP ESTIMATION

First, for a random vector $\vec{Y}_i = (Y_{i1}, ..., Y_{id})$ with i = 1, ..., n we estimate univariate cutpoints a_{ik} for j = 1, ..., d using empirical distribution:

$$\hat{a}_{j0} = 0, \hat{a}_{j1} = p_0, \hat{a}_{j2} = p_0 + p_1, ..., \hat{a}_{jK_j} = p_{j0} + ... + p_{j, K_j - 1} = 1$$
 (18)

with p_k being a sample proportion, $p_k = \frac{1}{n} \sum_{i=1}^n \mathbb{1}\{y_i = k\}$. Note that K_j depends on j; the variables do not need to have the same number of categories. Uniform cutpoints $a_{jk} = \Phi(\zeta_{jk})$ are then converted to corresponding cutpoints ζ_{jk} in N(0,1) with Φ^{-1} i.e. inverse standard normal cdf. With these held fixed, dependence parameters $\theta \in M_{d \times d}$ are estimated using MLE approach and maximising log-likelihood function:

$$\ell(\theta) = \sum_{i=1}^{n} \ln P(Y_{ij} = y_{ij}, j = 1, ..., d; \theta) = \sum_{i=1}^{n} \ln P(\vec{Y}_i = (y_1, ..., y_d), \theta)$$
(19)

The probability under the sum can be evaluated as (Panagiotelis 2012):

$$P(\vec{Y}_i = (y_1, ..., y_d); \theta) = \sum_{k_1 = 0, 1} ... \sum_{k_d = 0, 1} (-1)^{k_1 + ... + k_d} P(Y_1 \le y_1 - k_1, ..., Y_d \le y_d - k_d); \theta$$
 (20)

which for d = 2 and $\theta \in \mathbb{R}$ is in line with inclusion-exclusion principle:

 $^{^{7}}$ Or other copulas with properties similar to Gumbel like Galambos or Clayton.

$$P(\vec{Y}_{i} = (y_{1}, y_{2}); \theta) = P(Y_{1} \leq y_{1}, Y_{2} \leq y_{2}; \theta) - P(Y_{1} \leq y_{1}, Y_{2} \leq y_{2} - 1; \theta) -$$

$$-P(Y_{1} \leq y_{1} - 1, Y_{2} \leq y_{2}; \theta) + P(Y_{1} \leq y_{1} - 1, Y_{2} \leq y_{2} - 1; \theta) =$$

$$= C_{\theta}(a_{1, y_{1} + 1}, a_{2, y_{2} + 1}) - C_{\theta}(a_{1, y_{1} + 1}, a_{2, y_{2}}) - C_{\theta}(a_{1, y_{1}}, a_{2, y_{2} + 1}) + C_{\theta}(a_{1, y_{1}}, a_{2, y_{2}})$$

$$= C_{\theta}(a_{1, y_{1} + 1}, a_{2, y_{2} + 1}) - C_{\theta}(a_{1, y_{1} + 1}, a_{2, y_{2}}) - C_{\theta}(a_{1, y_{1}}, a_{2, y_{2} + 1}) + C_{\theta}(a_{1, y_{1}}, a_{2, y_{2}})$$

where $y_i = 0, ..., K_i - 1, y_2 = 0, ..., K_2 - 1$. One chooses copula family with the highest likelihood.

1.5. SIMULATION IN R

Estimation was conducted using R package "CopulaModel" developed by H. Joe and P. Krupskii. For 1-factor models, the following copulas were tested in the process, regardless of the initial diagnostics of the dataset: Gumbel, survival Gumbel, Gaussian, as well as *t* copulas with 2, 3, 4, 5, 7 and 9 degrees of freedom.

The algorithm for copula simulation is as follows. For each group of respondents univariate cutpoints are estimated based on the sample as in 18, and for each copula or a set of copulas d parameter values are estimated in line with the formula 19 for the log-likelihood function. It is possible to maximize the function numerically using the Newton-Raphson method but for large d it is extremely time-consuming. Inference Function of Margins (IFM) described by H. Joe (Joe 2005) was used, since d=24. This method is efficient regarding both computing time and asymptotic variance. Using the vector of parameters, a simulation is conducted to generate a twin dataset with the same number of observations whose multivariate distribution is given by the copula. One should notice that since the forms of bivariate copulas in 8, 10 and 12 denote continuous distributions, some figures have to be rounded up or down randomly. The obtained database depends on seed settings of a random number generator. Afterwards, the same diagnostics can be run on both original dataset and a simulated one for comparison.

2. HEALTH MODELING VIA 1-FACTOR COPULA MODEL

ELSA (English Longitudinal Study of Ageing⁸ is a survey of quality of life among older people in the UK. Waves 1 and 6 (2002, 2012) were downloaded from the UK Data Archive. Although the dataset allows longitudinal analyses, only cross-sectional were conducted to show if and how the conditions of the elderly have changed over time.

⁸ Marmot M., Oldfield Z., Clemens S., Blake M., Phelps A., Nazroo J., Steptoe A., Rogers N., Banks J. (2016), *English Longitudinal Study of Ageing*, Waves 0–7, 1998–2015 (data collection), 24th Edition, UK Data Service, SN: 5050, http://dx.doi.org/10.5255/UKDA-SN-5050–11.

2.1. DATA

The multivariate model comprises of 24 variables: 19 items describing control, autonomy, self-realization and pleasure, each rated on a scale from 1 to 4, self-reported health status, mobility, eyesight, hearing and pain rating.

Table 1. CASP-19 variables

C1	How often feels age prevents them from doing things they like
C2	How often feels what happens to them is out of their control
C3	How often feels free to plan for the future
C4	How often feels left out of things
A1	How often can do the things they want to do
A2	How often family responsibilities prevent them from doing things they want to do
А3	How often feels they can please themselves with what they do
A4	How often feels their health stops them from doing what they want to do
A5	How often shortage of money stops them doing things
P1	How often looks forward to each day
P2	How often feels that their life has meaning
P3	How often enjoys the things they do
P4	How often enjoys being in the company of others
P5	How often looks back on their life with a sense of happiness
S1	How often feels full of energy these days
S2	How often chooses to do things they have never done before
S3	How often feels satisfied with the way their life has turned out
S4	How often feels that life is full of opportunities
S5	How often feels the future looks good to them

The data has been adjusted to fit the assumptions in the model. The number of categories differed across variables and therefore was reduced to 4 by collapsing higher responses (pairing "very good" with "excellent" as one category). Therefore, some items, such as health, vision and hearing, are self-rated on the following scale: 1-"poor", 2-"fair", 3-"good", 4-"excellent". Both eyesight and hearing questions assume reporting the senses using everyday correcting devices such as glasses, contact lenses or hearing aid. Blind people fall into the first category of "poor" eyesight. Pain rating is derived from two separate questions: "Are you bothered by pain?" and "How much does it hurt?" by adding the fourth, "no pain", category. Therefore, the responses are: 1-"severe", 2-"moderate", 3-"mild", 4-"no pain". Mobility was measured by asking the respondents about how much difficulty they associate with walking for a quarter of a mile. The

possible answers were: 1-"unable to do it", 2-"much difficulty", 3-"some difficulty", 4-"no difficulty". Ordering of responses was reversed in some cases to assure positive dependence. After all necessary adjustments, the waves 1 and 6 consist of 4650 and 7915 observations, respectively, as shown in Table 2.

We analyze the distribution of the groups defined based on sex, age (50–64 years old group and 65+), employment (retired, employed, unemployed, disabled), as well as smoking (behavioral risk). This gives us 10 groups to analyze in each wave.

Table 2. Sample sizes by population groups

	size (wave 1)	% (wave 1)	size (wave 6)	% (wave 6)

total	7 915	

2.2. DESCRIPTIVE STATISTICS

As a first approximation, Tables 13 and 14 and Tables 10 and 11 contain information on, respectively, group means and differences if scale 1–4 of ordinal variables is used. Figure 2 presents it graphically.

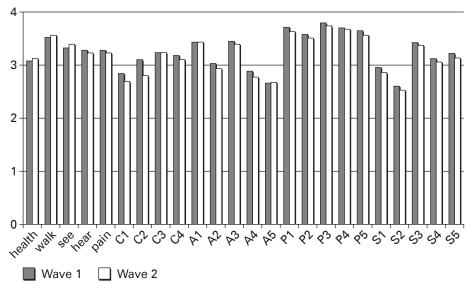

Figure 2. Mean values of variables in waves 1 and 6

Source: Own calculations based on the ELSA Wave 1 and Wave 6.

It can be easily inferred that, on average, younger people tend to feel better physically than older people, which does not, however, translate to better mental health. On the other hand, smoking can be seen related to both worse physical and mental condition. The people who still work are of better general health but not with respect to general happiness; here retired are better off. The unemployed are less satisfied than both mentioned groups and the disabled present the worst condition of all. There is no visible pattern to how men differ from women – each group dominates the other in nearly equal number of items and the differences are often insignificant.

Comparing between waves (Table 12), what stands out is a considerable decline (of more than 0.1) among the unemployed respondents which means that they feel worse than ten years ago. Items C1, C2, A4, S1 show noticeable decline in all groups which indicates that people may feel more tired and physically constrained by their conditions in wave 6 comparing to wave 1. In 2012 people of all ages over 50 reported significantly better health and mobility than in 2002. People older than 65 have bettered in eyesight as well, however, hearing worsened in both age groups. Control domain consisting of variables C1, C2, C3 and C4 experienced dramatic decrease regardless of the age of respondents; respondents feel less in control of their actions now. Two variables concerning autonomy, A1 and A5, improved for

65+ age group. The first indicator refers to a general power to do the things one wants to do and the latter indicates whether a respondent feels financial constraints. Indicators measuring pleasure experienced a slight decline over the period.

3. RESULTS

Table 3 presents bivariate count distributions of CASP-19 variables A5 and S5 simulated with various copulas, as well as observed distribution. A5 refers to financial constraints, whereas S5 refers to prospects for the future. Because item A5 is linked to negative events, the order of categories was reversed. The table illustrates how many respondents are estimated to fall into each bivariate category, e.g. in the original study there were 63 men who reported their money restrictions to occur "often" and who, simultaneously, never felt that their future looked good. On the other hand, there were 483 men who were optimistic about their future and did not feel constrained by money. From this initial diagnostics it seems that empirically A5 has more probability in the centre, it is therefore a discretised mean variable, whereas S5 witnesses more mass in extreme (maximum) values. This is why the joint probability is asymmetric and upper tail dependence is observed. Simulations with Gumbel copulas have more mass in the upper quadrant but the least in the lower quadrant of all estimated distributions. Gaussian copulas, on the other hand, underestimate the upper tails and shift the mass towards the middle categories, leaving little negative dependence. t copulas give the closest approximation compared to the other families -t(5)and t(7) seem to be the closest fits for males and t(4) or t(5) for females. The initial diagnostics show that the dependence of financial constraints and one's view about the future is not linear and is stronger for both those financially constrained and financially unconstrained. These non-linearities cannot be detected with the Gaussian model and cannot be seen if the data were dichotomized. With two four-categories variables there is nine different ways of where to put a cutoff (three different ways for one item given that they are in an increasing order so that 1 in the lower categories implies 1 in higher categories). In Table 4 we present the distribution of A5 and S5 among males after the following dichotomizations: (i) a respondent has health problems if he reports categories 2, 3, or 4 for both indicators (ii) a respondent has health problems if he reports categories 3, or 4 for both indicators (iii) a respondent has health problems if he reports category 4 for both indicators. Therefore, we observe three 2×2 distributions. Marginal distributions change, but the dependence structure changes too and it changes fundamentally. If cases (i) and (ii) are considered then we conclude that A5 and S5 are strongly related in the upper tail, on the other hand this is reversed for (iii). Clearly, dichotomization obscures the dependence structure. Furthermore, from policy point of view, the existence of tail dependence implies that, with marginals unchanged, there is a certain level of comorbidity in emotional health. Emotional health conditions tend to occur together and tend to *not* occur

Table 4. Males joint A5, S5 distribution after dichotomisation with different cut-off

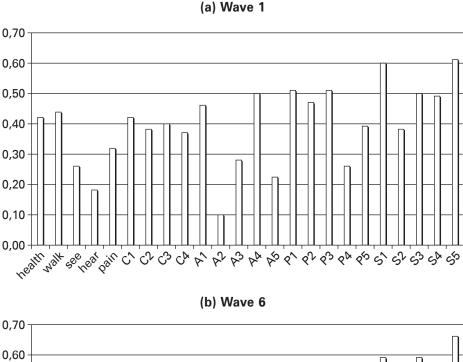

together. In line with inequality measurement theory axioms, such property of a health distribution implies that it is more unequal.

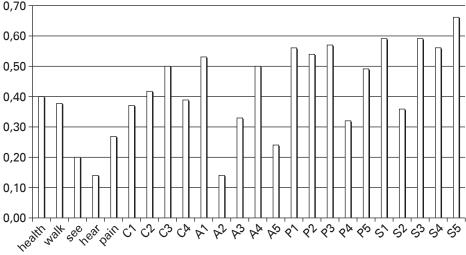

Tables 5 and 6 display absolute values of the log-likelihood function for all tested copulas and univariate distributions in both waves of the data. The smallest figures are emphasized in bold. Both waves are dominated by *t* copulas with 4 degrees of freedom; in wave 1 only the groups of employed, unemployed and disabled people can be estimated most accurately with a *t*(5) copula and in wave 6 there are two such groups, the females and the unemployed. All tested distributions are characterized with intermediate dependence in both upper and lower tail. Such interdependence is impossible to detect if the data are dichotomized and then aggregated. Furthermore, the results imply that the responses are the mixture of discreticised means which is typical for mixed populations (Nikoloulopoulos and Joe 2015). We thus find evidence that factor copula model based on *t* copulas works better for our health data than purely Gaussian model; the improvement is more evident for Wave 6 than Wave 1.

As to the interpretation of the factor, we analyze the values of copula parameters corresponding to the model with the maximum likelihood (Tables 16 and 17). The interpretation is available without the need for a varimax rotation typical of factor models. Parameters that can be compared between models are given on a Kendall's tau scale (Tables 18 and 19). The higher the copula parameter, the more dependent a given item on a factor, which provides for a factor's interpretation. Figure 3 illustrates the parameters for the groups of non-smokers (as they are most numerous). In wave 1 items S1 and S5 appear to be most linked with the factor. They describe a person's level of energy and views for the future, thus the factor can be interpreted as general optimism in life. In wave 6 there are more items with dependence parameters close to 0.6; these are S1, S3, S5, P1 and P3. The interpretation of factor one as measuring general optimism is now extended to cover life satisfaction and the feeling of enjoyment about things one does.

The most heterogeneity is found among groups based on employment status. In Wave 1 (Table 18) there is substantial dependence of general health status and mobility for both retired and disabled and much less for the employed group. In other words, among retired and disabled whether the person is mobile or not is related stronger to his/her subjective health status than in the employed group. Furthermore, these two are one of key health indicators for these two groups. The similar difference is observed for indicators C1 and C2 which measure how

Figure 3. Parameters on a Kendall's tau scale

much one feels constrained by age and feels lack of control. These two are more interdependent among retired and disabled than among employed group. In Wave 1 for the unemployed group items such as *P*1 and *P*3 appear as the most informative of the underlying factor, whereas for other groups all items in P

(pleasure) category are equally important. P1 and P3 measure the enjoyment one has about every day and things in life. In Wave 6, P1 becomes the key item for the employed group too. All in all, the employed group seems different in terms of emotional health comparing to other groups. The dependence parameters seem more evenly distributed in this group, suggesting that the underlying factor may point to a general level of well-being, whereas for other groups, factor's

interpretation may be more specific and focus mostly on physical limitations and the indicators for depression e.g. energy levels.

Tables 7 and 8 present univariate distributions of all items for two groups: males and females. There are only small differences in the original and estimated margins. Margins were estimated with t(4) and t(5) copulas for men and women respectively, with parameters given in table 17.

There is no coherent way to illustrate a 24-dimensional distribution, thus we present estimated bivariate margins for variables *health* and A4 (Table 9) which measures the feeling of autonomy. The two variables are expected to be dependent, since lower levels of general health imply e.g. mobility limitations. Indeed, a vast majority of probability mass is gathered near the main diagonal as can be seen in Table 9. For each decomposed group, the table contains output from a copula with the highest value of log-likelihood function (cf. table 6). The maximum deviation in all presented values is 8,11% (compared to the magnitude of each subsample) and average deviation is lower than 2%.

4. CONCLUSION

Considering causal links would add further layers of complexity to the model and is beyond the scope of this paper. However, there is still a lot to be learnt about the joint distribution of health. This is an area of active research in the last decade too as detailed information on health has become available. A disaggregated view of health will inform researchers and policymakers on most vulnerable groups (in terms of both worse unidimensional health distributions and the incidence of multiple health deprivations) and on the potential areas of intervention.

Factor copulas are indeed powerful and flexible tools in modeling multivariate data, including difficult cases of high-dimensional and ordinal data that defy regular procedures (see e.g. Oh and Patton 2015). They have been so far applied in psychometrics (Nikoloulopoulos and Joe 2015) and continuous stock returns (Krupskii and Joe 2013, 2015, Oh and Patton 2015). They are very flexible in modeling complex dependence with particular emphasis on tail dependence. In this paper we present their usefulness in modeling ordinal health data. They can detect complexities and nonlinearities in the data that are not detectable to the methods proposed in the health and health inequality measurement literature so far. We show that there is a potential in applying factor copula models to health data and provide evidence that richer models provide for a better fit. The presentation here should be developed in the following directions: (i) estimation of 2- and possibly 3-factor models (ii) estimation of structured factor copula models for ordinal data where the group structure (such as autonomy, control etc. in CASP-19) is taken into account in the statistical models (structured copulas have only been developed for continuous data (Krupskii and Joe 2015)). Structured factor copulas are extensions to the Gaussian bi-factor model covered by Gibbons i Hedeker (1992) and Holzinger and Swineford (1937). (iii) choosing different bivariate linking copulas in a given tree, which has to be done with caution as it obscures model comparisons. Concerning the latter, Table 10 illustrates bivariate distribution of variables C3 and S5. Clearly, they are upper dependent; the probability mass is

concentrated in the upper quadrant. Not surprisingly, the corresponding count figures delivered by the Gumbel copula provide the best fit.

Table 10. Comparison of modelling upper tail dependence of items C3 and S5

Another important extension of the model is the addition of regression parameters, not only for marginals (i.e. via probit regressions), but also for the dependence parameters, as dependence may potentially depend on a different set of covariates.

MODELOWANIE WSKAŹNIKÓW ZDROWOTNYCH ZA POMOCĄ KOPUŁ CZYNNIKOWYCH

STRESZCZENIE

W ostatniej dekadzie mamy dostęp do szczegółowych danych zdrowotnych (np.: badanie SHARE). Modelowanie łącznego rozkładu wielu wskaźników zdrowotnych nie jest łatwym zadaniem. Literatura nie jest duża i nie adresuje właściwie np.: struktury zależności między wskaźnikami. Współwystępowanie chorób jest zaś kluczowe dla wydatków na opiekę zdrowotną. Celem artykułu jest pokazanie, że zależności te występują w stopniu, który nie może być ignorowany oraz rozszerzenie literatury o metody, które modelują łączny rozkład zdrowia elastycznie i wydajnie obliczeniowo. Są to dostępne od niedawna tzw. pair-copula constructions (PCC) (Aas et al., 2009). Mogą one być użyte przy wielu wymiarach zdrowia, gdzie inne metody są niekonkluzywne (Duclos i Echevin, 2012). Na podstawie danych z English Longitudinal Study of Ageing (ELSA) nt. statusu zdrowotnego, mobilności, wzroku, słuchu czy zdrowia emocjonalnego, estymujemy jednoczynnikowy model (Nikoloulopoulos i Joe, 2015). Wskaźniki zdrowia wykazują zależność w ogonach; kopule t(4) i t(5) wykazują najlepsze dopasowanie. Szczegółowe zależności są nie do wykrycia przez niedawno rozwinięte podejścia (Makdisi i Yazbeck, 2014).

Słowa kluczowe: dane porządkowe, zdrowie, nierówności, kopuły czynnikowe. **JEL Classification:** I31. D63
